Spiny lobsters form an important component of the crustacean resources of our marine fisheries. It is second in importance to prawns in terms of commercial value and has an export market. The Central Marine Fisheries Research Institute has been carrying out researches on spiny lobster resources along our coast, their fishery, production and biology based on the natural stocks. Due to its high export value, there has been heavy pressure on these coastal stocks. (Table)

Six species of spiny lobsters of commercial importance occur in Indian waters and these are:

- *Panulirus homarus* (Linnaeus)
- *Panulirus polyphagus* (Herbst)
- *Panulirus penicillatus* (Oliver)
- *Panulirus ornatus* (Fabricius)
- *Panulirus versicolor* (Latreille)
- *Panulirus longipes* (Milne-Edwards)

While the Institute is working on the rational exploitation of the lobster stocks, it has also started programmes for developing proper techniques for their culture. The major constraints encountered in lobster culture are:

1. Our inadequate knowledge of their reproductive physiology
2. Protracted complex life cycle with larval phase extending to several months and problems of maintaining the larvae.
3. Nutritional (feed) requirements of larvae and adults.
4. Slow growth of lobsters from puerulus stage to maturation and harvestable sizes.
5. Behaviour of lobsters.

In fact, even in areas such as water quality requirements, diseases, and management techniques for lobster culture, our knowledge is still meagre. In view of these inadequacies, the Institute has given priority for the following:

- Collection and maintenance of brood stock
- Controlled breeding
- Larval rearing
- Culture of baby lobsters (puerulus) to commercial size.

The programme also involves a multi-disciplinary approach including researches on nutrition, pathology, physiology, endocrinology and genetics.

One of the first tasks undertaken was the collection and the rearing of puerulii and metamorphosed baby lobsters of *P. homarus* to maturation and harvestable sizes. It was possible to collect from the inshore waters as well as from special puerulii collectors operated from rafts used for open sea mussel culture puerulii and young lobsters and rear them to marketable size of 200 gm weight under experimental conditions in a period of 18 months. The growth rates in such culture operations with clam and mussel meat as feed were almost identical with that studied for growth obtaining in the natural population of *P. homarus*.

On an average, growth increment worked out to about 12 gm during each intermoult period, the moult frequency being around once every 30 to 55 days. Further increment of weight is also characterised by such a slow trend of growth.

In connection with the work on growth and reproductive physiology and endocrinology of *P. homarus*, recourse to the well-known and widely adopted technique of eye stalk ablation was resorted to. Such techniques are employed in studies on crustacean growth and reproduction in many parts of the world. The hormonal system in crustaceans involved in growth and reproduction is antagonistic and reproduction alternates with growth. There are the moulting hormone and the mould inhibiting hormone. Unlike in the case of vertebrates, particularly mammals, the endocrinology of crustaceans has been very little understood. The lobster culture programme in the Institute includes investigation on crustacean endocrinology in order to understand the hormonal regulation of growth and reproduction and to be able to manipulate these hormonal function, once they are clearly understood, to achieve higher growth rate and temporal control of reproduction.

In *P. homarus*, as in other crustaceans, the endocrine complex present in the eye stalk controls the secretion of hormone and hence the need to study this complex in detail. One of the well-known methods in endocrinology is to block the system and to observe the results. As an experimental procedure, the eye stalk is electrically cauterised or ablated to block the hormonal system and study the effects on growth and reproduction.

Fig. 7. An ablated lobster with antennule-like growth at the place of the ablated eye (Full view)

The higher rate of growth observed in such eye stalk ablated lobsters is of great significance in regard to our understanding the hormonal action on moulting and growth. Since faster growth is a phenomena related to increase in production, it is of importance in culture production.

The results have been spectacular and fully justify consideration as a major breakthrough in making spiny lobster culture a viable proposition. My colleagues Shri E.V. Radhakrishnan and Shri M. Vijayakumaran who have been working under my guidance have in a series of experiments conducted on individual as well as groups of lobsters employing the eye ablation technique demonstrated that:

1. In a group of 10 early juvenile lobsters each weighing about 84.5 gm, when ablated and reared in experimental techniques for 165 days attained a mean weight of 432 gm as compared to the growth increment of only 57 gm for the control group.
2. In another trial involving 14 lobsters the average growth increment was 110.6 gm in 108 days, the corresponding growth for the control lobsters being 37.5 gm.
3. With repetitive trials with different number...
Do lobsters feel pain when blinded?

Do lobsters, which are blinded as part of their growth, feel pain like humans do? This question has been debated for years. Some scientists believe that lobsters do feel pain, while others argue that they do not. The concept of "pain" is complex and may vary across different species. Lobsters have a unique method of detecting touch, which may not be comparable to human pain perception. Further research is needed to understand their response to pain.

Lobsters Are Human Too

A Giant Leap

Do lobsters feel pain when blinded?

Do lobsters, which are blinded as part of their growth, feel pain like humans do? This question has been debated for years. Some scientists believe that lobsters do feel pain, while others argue that they do not. The concept of "pain" is complex and may vary across different species. Lobsters have a unique method of detecting touch, which may not be comparable to human pain perception. Further research is needed to understand their response to pain.
of lobsters varying from 4 to 18, the growth increase in the eye stalk ablated lobsters recorded was between 1.45 and 2.5 gm/day, which in the controls was hardly 0.35 gm/day, all lobsters being fed ad libitum with clam meat.

4. In one experiment, a lobster with an initial weight of 254 gm attained 402 gm after a single moult in 31 days—a weight increase of 148 gm after a moult! These figures appear incredible as compared to hardly 12 gm increment in weight recorded in the inter-moult period of about one month in the controls as well as observed in the natural population.

These findings are remarkable since eye ablation technique in the American and Australian spiny lobsters P.argus and P.cyngus respectively did not yield results. This also definitely shows that culture of lobster from puerulus or early juveniles to a marketable size of 180 to 200 gm is possible in about 5 to 6 months and an almost doubling of weight is possible in another 2 to 3 months—in other words a 400 gm lobster in about 9 months!

From the time that the results of these experiments on spiny lobster growth adopting the eye ablation technique was announced, there has been a spate of letters in some of our national dailies questioning the ethics of such experiments with animals as this is considered as being against the tradition of our country (ref: p.4). In scientific research, experimentation with animals is inevitable. Such researches on other crustaceans have been in vogue for ages all over the world. Here the mandate has been to find out whether mariculture of spiny lobsters is a feasible proposition or not. Complacency due to the negative results obtained by scientists in the USA and Australia would have put the clock back several years. The success with eye ablation technique has now given us a clue as well as a lead to enhance our indepth studies on the endocrinological function of growth and maturation to map the endocrine organ, identify the hormones and understand their functions. The next step could be the acceleration or inhibition of growth/maturation as may be desired in the different phases of culture, through hormonal treatment and not consider eye ablation as the ultimate technology for obtaining higher production.

These researches no doubt open up the great possibilities of developing genetically faster growing strains for producing "Giant" lobsters and more than all make P.homarus a very good candidate species for culture. I would also like to announce that my colleagues Shri E.V.Radhakrishnan and Shri M.Vijayakumaran have also met with success in experiments carried out on 2 other species, P.ornatus and P.polyphagus. The lobster culture programme in the Institute is being accelerated to answer many of the problems that have come up in the course of the work undertaken during the last 2 years.
